Parametric versus Nonparametric)Chi-square(

Dr. Hamza Alduraidi

Parametric Assumptions

- The observations must be independent.
- Dependent variable should be continuous (I/R)
- The observations must be drawn from normally distributed populations
- These populations must have the same variances. Equal variance (homogeneity of variance)
- The groups should be randomly drawn from normally distributed and independent populations

e.g. Male X Female
Pharmacist X Physician
Manager X Staff

NO OVER LAP

Parametric Assumptions

- The independent variable is categorical with two or more levels.
- Distribution for the **two or more independent** variables is normal.

Advantages of Parametric Techniques

- They are more powerful and more flexible than nonparametric techniques.
- They not only allow the researcher to study the effect of many independent variables on the dependent variable, but they also make possible the study of their interaction.

Nonparametric Methods

- Nonparametric methods are often the only way to analyze nominal or ordinal data and draw statistical conclusions.
- Nonparametric methods require no assumptions about the population probability distributions.
- Nonparametric methods are often called distribution-free methods.
- Nonparametric methods can be used with small samples

Nonparametric Methods

- In general, for a statistical method to be classified as nonparametric, it must satisfy at least one of the following conditions.
  - The method can be used with nominal data.
  - The method can be used with ordinal data.
  - The method can be used with interval or ratio data when no assumption can be made about the population probability distribution (in small samples).

Non Parametric Tests

- Do not make as many assumptions about the distribution of the data as the parametric (such as *t* test)
  - Do not require data to be Normal
  - Good for data with outliers
- Non-parametric tests based on ranks of the data
  - Work well for ordinal data (data that have a defined order, but for which averages may not make sense).

Nonparametric Methods

- There is at least one nonparametric test equivalent to each parametric test
- These tests fall into several categories
  1. Tests of differences between groups (independent samples)
  2. Tests of differences between variables (dependent samples)
  3. Tests of relationships between variables

Summary Table of Statistical Tests

Level of Measurement	Sample Characteristics					Correlation
	1 Sampl e	2 Sample		K Sample (i.e., >2)		
		Independent	Dependent	Independent	Dependent	
Categorical or Nominal	X^2	X^2	Macnarmar's X^2	X^2	Cochran's Q	
Rank or Ordinal		Mann Whitney U	Wilcoxin Matched Pairs Signed Ranks	Kruskal Wallis H	Friendman's ANOVA	Spearman's rho
Parametric (Interval & Ratio)	z test or t test	t test between groups	t test within groups	1 way ANOVA between groups	1 way ANOVA (within or repeated measure)	Pearson's r
		Factorial (2 way) ANOVA				

Summary: Parametric vs. Nonparametric Statistics

- Parametric Statistics are statistical techniques based on assumptions about the population from which the sample data are collected.
  - Assumption that data being analyzed are randomly selected from a normally distributed population.
  - Requires quantitative measurement that yield interval or ratio level data.
- Nonparametric Statistics are based on fewer assumptions about the population and the parameters.
  - Sometimes called “distribution-free” statistics.
  - A variety of nonparametric statistics are available for use with nominal or ordinal data.

Chi-Square

Types of Statistical Tests

When running a *t test* and *ANOVA*

- We compare:
  - Mean differences between groups
- We assume
  - random sampling
  - the groups are homogeneous
  - distribution is normal
  - samples are large enough to represent population (>30)
  - DV Data: represented on an **interval or ratio** scale
- These are Parametric tests!

Types of Tests

When the assumptions are violated:

- Subjects were not randomly sampled
- DV Data:
  - Ordinal (ranked)
  - Nominal (categorized: types of car, levels of education, learning styles)
  - The scores are greatly skewed or we have no knowledge of the distribution

We use tests that are equivalent to t test and ANOVA

Non-Parametric Test!

Chi-Square test

- Must be a random sample from population
- Data must be in raw frequencies
- Variables must be independent
- A sufficiently large sample size is required (at least 20)
- Actual count data (not percentages)
- Observations must be independent.
- Does not prove causality.

Different Scales, Different Measures of Association

Scale of Both Variables	Measures of Association
Nominal Scale	Pearson Chi-Square: χ^2
Ordinal Scale	Spearman's rho
Interval or Ratio Scale	Pearson r

Important

- The chi square test can only be used on data that has the following characteristics:

The data must be in the form of frequencies

The frequency data must have a precise numerical value and must be organised into categories or groups.

The expected frequency in any one cell of the table must be greater than 5.

The total number of observations must be greater than 20.

Formula

$$X^2 = \frac{\sum (O - E)^2}{E}$$

X^2 = The value of chi square
O = The observed value
E = The expected value
$\sum (O - E)^2$ = all the values of (O – E) squared then added together

Chi Square Test of Independence

- Purpose
  - **To determine if two variables of interest independent (not related) or are related (dependent)?**
  - When the variables are independent, we are saying that knowledge of one gives us no information about the other variable. When they are dependent, we are saying that knowledge of one variable is helpful in predicting the value of the other variable.
  - Some examples where one might use the chi-squared test of independence are:
    - Is level of education related to level of income?
    - Is the level of price related to the level of quality in production?
- Hypotheses
  - The null hypothesis is that the two variables are independent. This will be true if the observed counts in the sample are similar to the expected counts.
    - **H_0: X and Y are independent**
    - **H_1: X and Y are dependent**

Chi Square Test of Goodness of Fit

- Purpose
  - **To determine whether an observed frequency distribution departs significantly from a hypothesized frequency distribution.**
  - **This test is sometimes called a One-sample Chi Square Test.**
- Hypotheses
  - The null hypothesis is that the two variables are independent. This will be true if the observed counts in the sample are similar to the expected counts.
    - **H_0: X follows the hypothesized distribution**
    - **H_1: X deviates from the hypothesized distribution**

Steps in Test of Hypothesis

1. Determine the appropriate test
2. Establish the level of significance: α
3. Formulate the statistical hypothesis
4. Calculate the test statistic
5. Determine the degree of freedom
6. Compare computed test statistic against a tabled/critical value

Determine Appropriate Test. 1

- Chi Square is used when both variables are measured on a nominal scale.
- It can be applied to interval or ratio data that have been categorized into a small number of groups.
- It assumes that the observations are randomly sampled from the population.
- All observations are independent (an individual can appear only once in a table and there are no overlapping categories).
- It does not make any assumptions about the shape of the distribution nor about the homogeneity of variances.

Establish Level of. 2 Significance

- α is a predetermined value
- The convention
  - $\alpha = .05$
  - $\alpha = .01$
  - $\alpha = .001$

:Determine The Hypothesis. 3 Whether There is an Association or Not

- H_o : The two variables are independent
- H_a : The two variables are associated

Calculating Test Statistics. 4

- Contrasts observed frequencies in each cell of a contingency table with expected frequencies.
- The expected frequencies represent the number of cases that would be found in each cell if the null hypothesis were true (i.e. the nominal variables are unrelated).
- Expected frequency of two unrelated events is product of the row and column frequency divided by number of cases.

$$F_e = F_r F_c / N$$

Expected frequency = $\frac{\text{row total x column total}}{\text{Grand total}}$

Calculating Test Statistics. 4

Continued

$$\chi^2 = \sum \left[\frac{(F_o - F_e)^2}{F_e} \right]$$

Calculating Test Statistics: 4

Continued

Observed frequencies

$$\chi^2 = \sum \left[\frac{(F_o - F_e)^2}{F_e} \right]$$

Expected frequency

Expected frequency

Determine Degrees. 5 of Freedom

$$df = (R-1)(C-1)$$

Number of levels in row variable

Number of levels in column variable

Compare computed test statistic. 6 against a tabled/critical value

- The computed value of the Pearson chi-square statistic is compared with the critical value to determine if the computed value is *improbable*
- The critical tabled values are based on sampling distributions of the Pearson chi-square statistic
- If calculated χ^2 is greater than χ^2 table value, reject H_o

χ^2

	$P(X \le x)$

10	2.558	3.247	3.940	4.865	15.99	18.31	20.48	23.21

Decision and Interpretation

- If the probability of the test statistic is less than or equal to the probability of the alpha error rate, we reject the null hypothesis and conclude that our data supports the research hypothesis. We conclude that there is a relationship between the variables.
- If the probability of the test statistic is greater than the probability of the alpha error rate, we fail to reject the null hypothesis. We conclude that there is no relationship between the variables, i.e. they are independent.

Example

- Suppose a researcher is interested in voting preferences on gun control issues.
- A questionnaire was developed and sent to a random sample of 90 voters.
- The researcher also collects information about the political party membership of the sample of 90 respondents.

Bivariate Frequency Table or Contingency Table

	Favor	Neutral	Oppose	f_{row}
Democrat	10	10	30	50
Republican	15	15	10	40
f_{column}	25	25	40	n = 90

Bivariate Frequency Table or Contingency Table

Chi-Square Tests

	Value	df	Asymp. Sig. (2-sided)
Pearson Chi-Square	2.821[a]	2	.244
Likelihood Ratio	2.815	2	.245
Linear-by-Linear Association	.832	1	.362
N of Valid Cases	606		

a. 0 cells (.0%) have expected count less than 5. The minimum expected count is 70.63.

The probability of the chi-square test statistic (chi-square=2.821) was p=0.244, greater than the alpha level of significance of 0.05. The null hypothesis that differences in "degree of religious fundamentalism" are independent of differences in "sex" is not rejected.

The research hypothesis that differences in "degree of religious fundamentalism" are related to differences in "sex" is not supported by this analysis.

Thus, the answer for this question is False. We do not interpret cell differences unless the chi-square test statistic supports the research hypothesis.
