

Diuretics overview (first 14 slides)

Diuretics increase excretion of fluid from inside (interstitium & plasma) to outside (urine).

- A **Natri-uretic** increases excretion of **Na⁺** and **water**.

Where do they work?

At the reabsorption stage, by blocking reabsorption of water and salts (mainly by blocking ion transporters)

- They often change urine pH and the ionic composition of urine and blood.
- Water, digitalis, caffeine and theophylline have diuretic activity, but are **not diuretics**.

Used for
Disturbance of
water and salt
(retention).

Thiazides
diuretics are
first line
therapy of HTN

Diuretics Safe
Cheap

Decrease risk of
MI, strokes, and
CVD in HTN
patients

Everywhere.
They act on
multiple sites of
the nephron

Mechanism of Diuretics Antihypertensive action

Decrease diastolic by: decreasing plasma volume and thus the cardiac output and eventually the BP

- Can cause reactive peripheral resistance that goes away with chronic use.

Decrease diastolic by: secretion of PGs, causing vasodilation

Diuretic therapy cautions

Excessive diuretic usage may lead to a decrease in the blood volume which could cause:

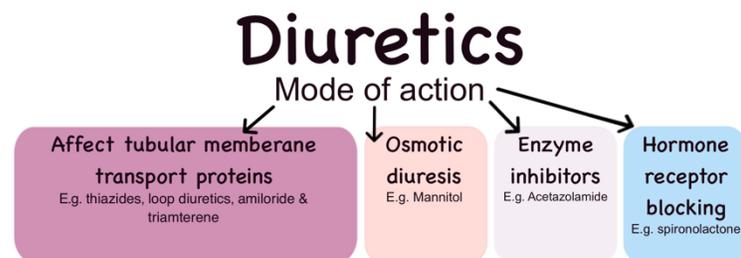

1. **Reduction in the perfusion of vital organs.** [using diuretics to treat edema requires careful monitoring of the patient's hemodynamic status and an understanding of the pathophysiology of the underlying condition]
2. Hypotension and collapse
3. Increased blood viscosity due to an increase in erythro- and thrombocyte concentration, which could lead to an increased risk of intravascular coagulation or thrombosis

Classification:

By: Site of action, mechanism of action or potency

Diuretic resistance causes (Therapeutic Failure)

1. Continued ingestion of salt
2. Impairment of organic acid secretion mechanisms in the proximal tubules
3. Secondary hyperaldosteronism
4. Lowered renal blood flow causing increased Na⁺ reabsorption (post-diuretic salt retention).
5. Lowered bioavailability of the drug.

Management of diuretic resistance

Restriction of sodium intake, changes in dose, changes in timing, and combination of diuretic therapy.

Macula densa cells work in the nephron:

Macula Densa

Monitoring of NaCl in the loop of henle

Increased [NaCl] (+)

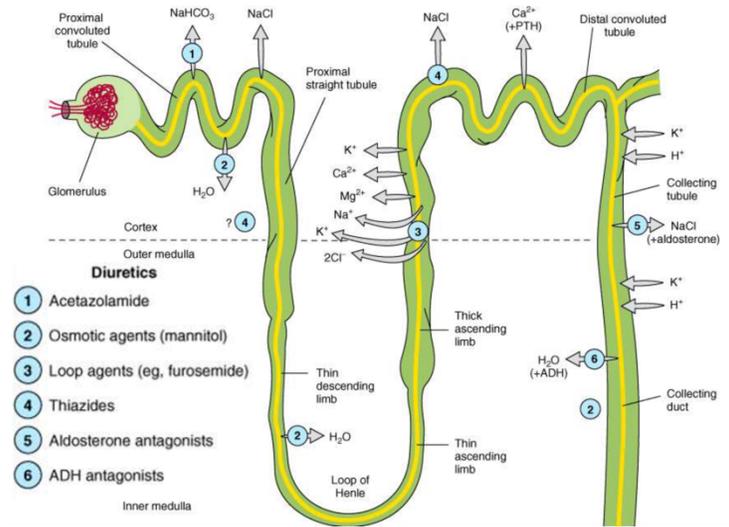

Send information (through adenosine) to the afferent arteriole causing its contraction & resulting in a decreased GFR.

(-) Decreased [NaCl]

Send information to juxtaglomerular cells causing them to release renin → Na⁺ Retention

This photo shows site of action of each diuretic class:

Other agents of diuretic activity:

Caffeine: weak diuretic, it weakly blocks adenosine receptors that participate in the control of proximal tubule Na⁺ reabsorption.

Rolofylline: an adenosine A1 receptor antagonist (A new class), it has a potent vasomotor effects (dilation) in the nephron and blunts proximal tubule and collecting duct NaCl reabsorption.

Prostaglandins

- Five subtypes (PGE, PGI, PGD, PGF, and thromboxanes) are synthesized in the kidney.
- The PGE participate in the regulation of salt reabsorption and play a role in the activity of certain diuretics.
- PGE₂ decreases both Na⁺ reabsorption in the Thick ascending limb of Henle's loop and ADH-mediated water transport in collecting tubules.
